

ON THE VARIATIONS OF THE PRINCIPAL EIGENVALUE WITH RESPECT TO A PARAMETER IN GROWTH-FRAGMENTATION MODELS*

FABIEN CAMPILLO[†], NICOLAS CHAMPAGNAT[‡], AND CORALIE FRITSCH[§]

Abstract. We study the variations of the principal eigenvalue associated to a growth-fragmentation-death equation with respect to a parameter acting on growth and fragmentation. To this aim, we use the probabilistic individual-based interpretation of the model. We study the variations of the survival probability of the stochastic model using a generation by generation approach. Then, making use of the link between the survival probability and the principal eigenvalue established in a previous work, we deduce the variations of the eigenvalue with respect to the parameter of the model.

Keywords. Growth-fragmentation model, eigenproblem, integro-differential equation, invasion fitness, individual-based model, infinite dimensional branching process, piecewise-deterministic Markov process, bacterial population.

AMS subject classifications. 35Q92, 45C05, 60J80, 60J85, 60J25, 92D25.

1. Introduction

In biology, microbiology and medicine, diverse models are used to describe structured populations. For example the growth of a bacterial population or of tumor cells can be represented, in a constant environment, by the following growth-fragmentation-death equation [1, 7, 9, 10, 15, 17, 27]

$$\frac{\partial}{\partial t} m_t(x) + \frac{\partial}{\partial x} (g(x) m_t(x)) + (b(x) + D) m_t(x) = 2 \int_x^M \frac{b(z)}{z} q\left(z, \frac{x}{z}\right) m_t(z) dz,$$

which describes the time evolution of the mass density m_t of the population of cells which is subject to growth at speed g , cell division at rate b , with daughter cells generated by a division kernel q and death at rate D . In order to study the asymptotic growth of the population, the eigenproblem associated to this equation is generally considered. The eigenvalue, also called Malthus parameter in this context, gives the asymptotic global growth rate of the population and allows one to determine if the environment favors the development of the population.

Biologically, it is interesting to study the variation of this growth rate when the environment is changed (either by the action of an experimentalist or due to fluctuations of external conditions). In this article, we consider the model described previously, in which the growth function and the division rate depend on an environmental parameter S describing the constant environment. The death rate is assumed independent of S since we have in mind chemostat in which death is due to dilution at fixed rate. This parameter can, for example, represent an external resource or the influence of other populations supposed to be at equilibrium. The study of the influence of this

parameter on the growth of the population is a question of biological interest for a better understanding of the model, but also of numerical interest, for example, for the study of mutant invasions in adaptive dynamics problems [11].

This new question seems to be difficult to approach with standard deterministic mathematical tools where, to our knowledge, no result is available except a study of the influence of asymmetric division in [20, 21] and an asymptotical study of the influence of the parameters by [2]. See also [24] for a study of the impact of the variability in cells' aging and growth rates as well as [5] for comparison of Perron eigenvalue (for constant in time birth and death rates) and Floquet eigenvalue (for periodic birth and death rates). The approach that we propose in this article uses the probabilistic interpretation of the growth-fragmentation-death equation under the form of a discrete stochastic individual-based model. This class of piecewise deterministic Markov processes is studied a lot, with recent interest focused on the estimation of the parameters of the model [8, 13, 14]. In this individual-based model, the growth of the population is determined by its growth rate, but also by its survival probability in some constant environment. The link between the eigenvalue of the deterministic model and the survival probability of the stochastic model, which correspond to two different definitions of the biological concept of invasion fitness [16, 18], was established in [3]. Our goal is to use this link to deduce variation properties of the eigenvalue with respect to the environmental parameter S from the variations on the survival probability. The probabilistic invasion fitness allows the use of a generation by generation approach, which is more difficult to apply to the eigenproblem since generations overlap. Using this approach, the variations of the survival probability can be obtained by applying a coupling technique to the random process.

In an adaptive dynamics context, the variation of both invasion fitnesses are numerically very useful. For instance, considering the time evolution of a bacterial population in a chemostat, the invasion fitness determines if some mutant population can invade a resident population when a mutation occurs [19]. The invasion fitness may be defined as the growth rate of the mutant population in the equilibrium environment determined by the resident population. In this example, the environmental parameter S represents the substrate concentration at the equilibrium of the resident population. When the mutant population appears in the chemostat its size is small. Hence, its influence on the resident population and on the resource concentration can be neglected, which means that the substrate concentration S can be assumed to be constant as long as the mutant population is small. Moreover, due to the small number of mutant individuals, it is essential to use a stochastic model [4, 12]. However, the stochastic invasion fitness is numerically less straightforward to compute than the deterministic one. The mutual variations of both invasion fitnesses established in this article considerably simplifies the numerical analysis of a mutant invasion since the problem is reduced to the computation of a single eigenvalue that characterizes the possibility of invasion of the mutant population [11].

In Section 2, we present the deterministic and the stochastic versions of our growth-fragmentation-death model. We give the definitions of invasion fitness in both cases: for the stochastic case it is defined as the survival probability, and for the deterministic case it corresponds to the eigenvalue of an eigenproblem. We extend some results from [3], in particular Theorem 2.1 linking these two invasion fitnesses, to our more general context. Section 3.1 is devoted to the monotonicity properties of the survival probability of the stochastic model with respect to the initial mass and the death rate. In Section 3.2 we prove, under suitable assumptions, the monotonicity of the survival probability with respect to the environmental parameter S . In Section 3.3, we deduce from the previous

results and from the link between the two invasion fitnesses, the monotonicity of the eigenvalue with respect to S . Our assumptions are based on the realistic biological idea that the larger a bacterium is the faster it divides, and the larger the parameter S is the faster a bacterium grows. This is biologically consistent in the case where S represents the substrate concentration. The monotonicity of fitnesses is obtained under additional assumptions which are detailed in the following sections. We extend this result assuming a particular form of the growth rate g and give a more general approach in Section 3.4.

2. Models description

In this Section we present two descriptions of the growth-fragmentation-death model. This model is the one studied in [3], in which we add a dependence on a one-dimensional environmental parameter S , which is supposed to be fixed in time. In Section 3, we study the variation of the invasion possibility of the population (whose definition depends on the considered description) with respect to S for both descriptions.

2.1. Basic mechanisms. We consider models in which each individual is characterized by its mass $x \in [0, M]$, where M is the maximal mass of individuals, and is affected by the following mechanisms:

- (1) **Division:** each individual of mass x divides at rate $b(S, x)$, into two individuals with masses αx and $(1 - \alpha)x$, where the proportion α is distributed according to the probability distribution $Q(x, d\alpha) = q(x, \alpha) d\alpha$ on $[0, 1]$.

- (2) **Death:** each individual dies at rate D .
- (3) **Growth:** between division and death times, the mass of an individual grows at speed $g: \mathbb{R}_+ \times [0, M] \rightarrow \mathbb{R}_+$ depending on an environmental parameter S , i.e.

$$\frac{d}{dt}x_t = g(S, x_t). \tag{2.1}$$

In this model, the environmental parameter S is fixed in time, and individuals do not interact with each other. This means that the resource S is not limiting for the growth of the population, this is the case, for example, if the resource is continuously kept at the same level or resource consumption is negligible with respect to the resource quantity. This model is relevant for a population with few individuals in a given environment where resource consumption is low.

For any $S > 0$, let A_t^S be the flow associated to an individual’s mass growth in the environment S , i.e. for any $x \in (0, M)$ and $t \geq 0$,

$$A_t^S(x) = x + \int_0^t g(S, A_u^S(x)) du. \tag{2.2}$$

Throughout this paper we assume the following set of assumptions.

ASSUMPTIONS 2.1.

- (1) For any $x \in [0, M]$, the kernel $q(x, \cdot)$ is symmetric with respect to $1/2$:

$$q(x, \alpha) = q(x, 1 - \alpha), \quad \forall \alpha \in [0, 1]$$

and $\int_0^1 q(x, \alpha) d\alpha = 1$.

- (2) For any $\alpha \in [0, 1]$, the function $x \mapsto q(x, \alpha)$ is continuous on $[0, M]$.
- (3) There exists a function $\bar{q}: [0, 1] \mapsto \mathbb{R}_+$ such that $q(x, \alpha) \leq \bar{q}(\alpha)$ for any $x \in (0, M)$ and $\int_0^1 \bar{q}(\alpha) d\alpha < +\infty$.
- (4) $g(S, 0) = g(S, M) = 0$ and $g(S, x) > 0$ for any $x \in (0, M)$ and $S > 0$.
- (5) $g(S, \cdot) \in C[0, M] \cap C^1(0, M)$, where $C[0, M]$ and $C^1(0, M)$ respectively represent sets of continuous functions on $[0, M]$ and continuously differentiable functions on $(0, M)$.
- (6) $b(S, \cdot) \in C[0, M]$, and there exists $m_{\text{div}} \in [0, M)$ and $\bar{b} > 0$ such that

$$\begin{aligned}
 b(S, x) &= 0 \text{ if } x \leq m_{\text{div}}, \\
 0 < b(S, x) &\leq \bar{b} \text{ if } x \in (m_{\text{div}}, M).
 \end{aligned}$$

Assumptions 2.1-(5) and 2.1-(4) ensure the existence and uniqueness of the growth flow defined by equation (2.2) for $x \in (0, M)$ until the exit time $T_{\text{exit}}(x) := \inf\{t > 0 \mid A_t^S(x) \geq M\}$ of $(0, M)$, and they ensure that $A^S \in C^1(\mathcal{D})$ with $\mathcal{D} = \{(t, x), t < T_{\text{exit}}(x)\}$ [6, Th. 6.8.1]. We define this flow as constant when it starts from M . Note that the exit time $T_{\text{exit}}(x)$ is infinite if the convergence $\lim_{x \rightarrow M} g(S, x) = 0$ is sufficiently fast (see for example [3, Assumption 3.] for more details). Assumption (4) means that the maximal biomass of an individual is the same for any concentration of resources. This may not be true in general, but we can always change the scale of biomass for each value of S so that the maximal value of x is always M and modify the growth and birth parameters accordingly. This is what we shall assume in the sequel.

2.2. Growth-fragmentation-death integro-differential model. The deterministic model associated to the previous mechanisms is given by the integro-differential equation

$$\frac{\partial}{\partial t} m_t^S(x) + \frac{\partial}{\partial x} (g(S, x) m_t^S(x)) + (b(S, x) + D) m_t^S(x) = 2 \int_x^M \frac{b(S, z)}{z} q\left(z, \frac{x}{z}\right) m_t^S(z) dz, \tag{2.3}$$

where $m_t^S(x)$ represents the density of individuals with mass x at time t evolving in the environment determined by S , with a given initial condition m_0^S .

Let \mathcal{G}_S be the non local transport operator such that $\partial_t m_t^S(x) = \mathcal{G}_S m_t^S(x)$: for any $f \in C^1(0, M)$, $x \in (0, M)$,

$$\mathcal{G}_S f(x) \stackrel{\text{def}}{=} -\partial_x (g(S, x) f(x)) - (D + b(S, x)) f(x) + 2 \int_x^M \frac{b(S, z)}{z} q\left(z, \frac{x}{z}\right) f(z) dz, \tag{2.4}$$

and \mathcal{G}_S^* its adjoint operator defined for any $f \in C^1(0, M)$, $x \in (0, M)$ by

$$\mathcal{G}_S^* f(x) \stackrel{\text{def}}{=} -(D + b(S, x)) f(x) + g(S, x) \partial_x f(x) + 2b(S, x) \int_0^1 q(x, \alpha) f(\alpha x) d\alpha. \tag{2.5}$$

We consider the eigenproblem

$$\mathcal{G}_S \hat{u}_S(x) = \Lambda_S \hat{u}_S(x), \tag{2.6a}$$

$$\lim_{x \rightarrow 0} g(S, x) \hat{u}_S(x) = 0, \quad D + \Lambda_S > 0, \quad \hat{u}_S(x) \geq 0, \quad \int_0^M \hat{u}_S(x) dx = 1 \tag{2.6b}$$

and the adjoint problem

$$\mathcal{G}_S^* \hat{v}_S(x) = \Lambda_S \hat{v}_S(x), \quad \hat{v}_S(x) \geq 0, \quad \int_0^M \hat{v}_S(x) \hat{u}_S(x) dx = 1. \tag{2.7}$$

The eigenvalue Λ_S is then interpreted as the exponential growth rate (or decay rate if it is negative) of the population.

In the rest of the paper we will assume that the following assumption is satisfied.

ASSUMPTION 2.2. *For any $S > 0$, the system (2.6)–(2.7) admits a solution $(\hat{u}_S, \hat{v}_S, \Lambda_S)$ such that $\hat{u}_S \in C^1(0, M)$ and $\hat{v}_S \in C[0, M] \cap C^1(0, M)$.*

In [3], we have given some conditions under which this assumption holds (see also [7, 9] for slightly different models and [15, 22, 26] for exponential stability of the eigenfunctions).

2.3. Growth-fragmentation-death individual-based model. The mechanisms described in Section 2.1 can also be represented by a stochastic individual-based model, where the population at time t is represented by the counting measure

$$\eta_t^S(dx) \stackrel{\text{def}}{=} \sum_{i=1}^{N_t} \delta_{X_t^i}(dx), \tag{2.8}$$

where $N_t = \int_0^M \eta_t^S(dx)$ is the number of individuals in the population at time t and $(X_t^i, i = 1, \dots, N_t)$ are the masses of the N_t individuals (arbitrarily ordered).

The stochastic individual-based model is relevant for small population whereas the deterministic one is relevant for large population [4].

The process $(\eta_t^S)_{t \geq 0}$ is defined by

$$\begin{aligned} \eta_t^S = & \sum_{j=1}^{N_0} \delta_{A_t^S(X_0^j)} + \iiint\limits_{[0,t] \times \mathbb{N}^* \times [0,1]^3} 1_{\{j \leq N_{u^-}\}} 1_{\{\theta_1 \leq b(S, X_{u^-}^j)/\bar{b}\}} 1_{\{\theta_2 \leq q(X_{u^-}^j, \alpha)/\bar{q}(\alpha)\}} \left[-\delta_{A_{t-u}^S(X_{u^-}^j)} \right. \\ & \left. + \delta_{A_{t-u}^S(\alpha X_{u^-}^j)} + \delta_{A_{t-u}^S((1-\alpha)X_{u^-}^j)} \right] \mathcal{N}_1(du, dj, d\alpha, d\theta_1, d\theta_2) \\ & - \iint\limits_{[0,t] \times \mathbb{N}^*} 1_{\{j \leq N_{u^-}\}} \delta_{A_{t-u}^S(X_{u^-}^j)} \mathcal{N}_2(du, dj) \end{aligned} \tag{2.9}$$

where $\mathcal{N}_1(du, dj, d\alpha, d\theta_1, \theta_2)$ and $\mathcal{N}_2(du, dj)$ are two independent Poisson random measures defined on $\mathbb{R}_+ \times \mathbb{N}^* \times [0, 1] \times [0, 1] \times [0, 1]$ and $\mathbb{R}_+ \times \mathbb{N}^*$, corresponding respectively to the division and death mechanisms, with respective intensity measures

$$n_1(du, dj, d\alpha, d\theta) = \bar{b} du \left(\sum_{\ell \geq 1} \delta_\ell(dj) \right) \bar{q}(\alpha) d\alpha d\theta_1 d\theta_2, \tag{2.10}$$

$$n_2(du, dj) = D du \left(\sum_{\ell \geq 1} \delta_\ell(dj) \right), \tag{2.11}$$

(see [3, 4] for more details).

This population process can be seen as a multitype branching process with a continuum of types. We are interested in its survival probability.

We suppose that, at time $t=0$, there is only one individual, with mass x_0 , in the population, i.e.

$$\eta_0^S(dx) = \delta_{x_0}(dx).$$

The extinction probability of the population with initial mass x_0 is

$$p^S(x_0) \stackrel{\text{def}}{=} \mathbb{P}_{\delta_{x_0}}^S(\exists t > 0, N_t = 0),$$

where $\mathbb{P}_{\delta_{x_0}}^S$ is the law of the process $(\eta_t^S)_{t \geq 0}$ under the initial condition $\eta_0^S = \delta_{x_0}$. The survival probability is then given by $\mathbb{P}_{\delta_{x_0}}^S(\text{survival}) = 1 - p^S(x_0)$.

We define the n -th generation as the set of individuals descended from a division of one individual of the $(n-1)$ -th generation. The zeroth generation corresponds to the initial population. We denote by Z_n the number of individuals in the n -th generation and we define the probability of extinction before the n -th generation by

$$p_n^S(x_0) \stackrel{\text{def}}{=} \mathbb{P}_{\delta_{x_0}}^S(Z_n = 0), \quad n \in \mathbb{N}.$$

It is obvious that

$$\lim_{n \rightarrow \infty} p_n^S(x_0) = p^S(x_0).$$

Let τ be the stopping time of the first event (division or death). Then at time τ the population is given by

$$\eta_\tau^S \stackrel{\text{def}}{=} \begin{cases} 0 & \text{if death,} \\ \delta_{X_1} + \delta_{X_2} & \text{if division,} \end{cases} \tag{2.12}$$

with $X_1 = \alpha A_\tau^S(x_0)$ and $X_2 = (1-\alpha) A_\tau^S(x_0)$ where the proportion α is distributed according to the kernel $q(A_\tau^S(x_0), \alpha) d\alpha$.

Applying the Markov property at time τ and using the independence of particles, it is easy to prove (see [3]) that for any $x \in [0, M]$ and $n \in \mathbb{N}^*$

$$p_n^S(x) = D \int_0^\infty e^{-Dt} e^{-\int_0^t b(S, A_u^S(x)) du} dt + \int_0^\infty b(S, A_t^S(x)) e^{-\int_0^t b(S, A_u^S(x)) du - Dt} \int_0^1 q(A_t^S(x), \alpha) p_{n-1}^S(\alpha A_t^S(x)) p_{n-1}^S((1-\alpha) A_t^S(x)) d\alpha dt. \tag{2.13}$$

with $p_0^S(x) = 0$. It can then be deduced [3, Proposition 3] that p^S is the minimal non negative solution of

$$p^S(x) = \int_0^\infty D e^{-Dt} e^{-\int_0^t b(S, A_u^S(x)) du} dt + \int_0^\infty b(S, A_t^S(x)) e^{-\int_0^t b(S, A_u^S(x)) du - Dt} \int_0^1 q(A_t^S(x), \alpha) p^S(\alpha A_t^S(x)) p^S((1-\alpha) A_t^S(x)) d\alpha dt, \tag{2.14}$$

in the sense that for any non negative solution \tilde{p} we have $\tilde{p} \geq p^S$.

REMARK 2.1. By a change of variable, we have

$$p^S(x) = \int_x^M \frac{D}{g(S,y)} e^{-\int_x^y \frac{b(S,z)+D}{g(S,z)} dz} dy + \int_x^M \frac{b(S,y)}{g(S,y)} e^{-\int_x^y \frac{b(S,z)+D}{g(S,z)} dz} \int_0^1 q(y,\alpha) p^S(\alpha y) p^S((1-\alpha)y) d\alpha dy.$$

Therefore, the extinction probability is a solution of

$$g(S,x)\partial_x p^S(x) + D(1-p^S(x)) + b(S,x) \left\{ \int_0^1 q(x,\alpha) p^S(\alpha x) p^S((1-\alpha)x) d\alpha - p^S(x) \right\} = 0.$$

For any $x \in]0, M[$ and $y > 0$ such that $x \leq y$, let $t_S(x, y)$ be the first hitting time of y by the flow $A_t^S(x)$, i.e.

$$t_S(x, y) \stackrel{\text{def}}{=} \inf\{t \geq 0, A_t^S(x) = y\} = \begin{cases} \tilde{A}_{S,x}^{-1}(y), & \text{if } x \leq y < M, \\ +\infty, & \text{if } y \geq M, \end{cases} \tag{2.15}$$

where $\tilde{A}_{S,x}^{-1}$ is the inverse function of the C^1 -diffeomorphism $t \mapsto A_t^S(x)$.

In [3], we have made the link between the survival probability of the stochastic process and the eigenvalue of the deterministic model, given by the theorem below. This result was proved for a kernel $q(x, \cdot)$ which does not depend on $x \in (0, M)$, but it can easily be extended to our case where $q(x, \cdot)$ depends on the mass x at the division time as explained below.

THEOREM 2.1 (Campillo, Champagnat, Fritsch (2016)). *Under Assumptions 2.1 and 2.2, we have the following relation between the two invasion criteria*

$$\Lambda_S > 0 \iff \mathbb{P}_{\delta_x}^S(\text{survival}) > 0, \forall x \in (0, M).$$

Note that, contrary to the works [7,9,15,22,26], we assume here a compact set $[0, M]$ of biomasses to keep things simple in the sequel. The extension of our approach to a non-compact case would require us to identify the good assumptions at infinity for the last result to hold (the rest of our arguments should work similarly). The last problem is not so easy because it strongly depends on the growth at infinity of the eigenfunctions \hat{u} and \hat{v} of Assumption 2.2. Note in addition that the problem of existence of these eigenfunctions also requires a careful study at infinity (see [9]).

Proof. The key argument of the proof is that the process $(e^{-\Lambda_S t} \sum_{i=1}^{N_t} \hat{v}_S(X_t^i))_{t \geq 0}$ is a $\mathbb{P}_{\delta_x}^S$ -martingale such that

$$e^{-\Lambda_S t} \sum_{i=1}^{N_t} \hat{v}_S(X_t^i) \xrightarrow[t \rightarrow \infty]{} \mathcal{Z} \quad \mathbb{P}_{\delta_x}^S\text{-a.s.}$$

where \mathcal{Z} is an integrable random variable (see [3, Theorem 2 and Lemma 3]). The arguments used in [3] to prove that

- (1) if $\Lambda_S > 0$ then $\mathbb{P}_{\delta_x}^S(\text{survival}) > 0$ for any $x \in (0, M)$
- (2) if $\Lambda_S < 0$ then $\mathbb{P}_{\delta_x}^S(\text{survival}) = 0$ for any $x \in [0, M]$

can be directly applied to a kernel $q(x, \cdot)$ depending on the mass x of the cell which divides. The first statement is proved using the fact that \mathcal{Z} is bounded in L^2 if $\Lambda_S > 0$, while the second statement comes from the inequality

$$\mathbb{E}_{\delta_x}(N_t) \leq C_x e^{\Lambda_S t}, \quad \forall t \geq 0$$

where $C_x > 0$ is a constant depending on the initial mass $x \in (0, M)$. Its proof in [3] is technical, but the extension to kernels q depending on x is straightforward.

The only difficulty concerns the third point of the proof of [3, Theorem 2] in which we prove that if $\Lambda_S = 0$ then $M_t^\varepsilon \rightarrow 0$ a.s. with M_t^ε being the number of individuals having mass in $[\varepsilon, M - \varepsilon]$ at time t for $0 < \varepsilon < \frac{M}{2}$. Then the fourth point of the proof, stating that $M_t^\varepsilon \rightarrow 0$ implies extinction, follows similarly. The main idea of this fourth step is that the number of individuals M_t^ε cannot indefinitely stay in a compact subset $\{1, 2, \dots, c\}$ of \mathbb{N} for either $\limsup_{t \rightarrow \infty} M_t^\varepsilon = \infty$ or $M_t^\varepsilon \rightarrow 0$ a.s. But $\limsup_{t \rightarrow \infty} M_t^\varepsilon = \infty$ contradicts the fact that \mathcal{Z} is integrable if $\Lambda_S = 0$, hence $M_t^\varepsilon \rightarrow 0$ a.s.

For the proof of the third point (see details in [3]), it suffices that for $c > 0$, there exists t_0 such that

$$1 > \gamma := \inf_{\varepsilon \leq x \leq M - \varepsilon} \mathbb{P}_{\delta_x}^S(M_{t_0}^\varepsilon \geq c) > 0. \quad (2.16)$$

If $q(x, \cdot) = q(\cdot)$ is independent of the mother mass, it is sufficient to take $\varepsilon > 0$ such that $x \in (\varepsilon, M - \varepsilon)$ and $q([\varepsilon/(M - 2\varepsilon), 1/2]) > 0$ to obtain inequality (2.16) for one t_0 . In our case, the last condition must be replaced by $\inf_{\varepsilon \leq x \leq M - \varepsilon} q(x, [\varepsilon/(M - 2\varepsilon), 1/2]) > 0$ for some $\varepsilon > 0$. Note that the infimum above is reached at some $x_0(\varepsilon) \in [\varepsilon, M - \varepsilon]$, by Assumptions 2.1-(2) and (3). Therefore, we proceed by contradiction and assume that for all $\varepsilon > 0$, there exists $x_0(\varepsilon) \in [\varepsilon, M - \varepsilon]$ such that $q(x_0(\varepsilon), \alpha) = 0$ for almost all $\alpha \in \left[\frac{\varepsilon}{M - 2\varepsilon}; \frac{1}{2}\right]$. Then, from the sequence $(x_0(\frac{1}{n}))_n$, we can extract a subsequence which converges towards x_0^* . By continuity of $x \mapsto q(x, \alpha)$, we then get $q(x_0^*, \alpha) = 0$ for almost all $\alpha \in (0, 1)$. Hence $\int_0^1 q(x_0^*, \alpha) d\alpha = 0$, which contradicts Assumptions 2.1-(1). \square

3. Variations of the invasion fitnesses with respect to the environmental variable

Our goal is to study the variation of Λ_S with respect to S . For this, we start by studying the monotonicity properties of the survival probability in the stochastic model.

3.1. Monotonicity properties with respect to the initial mass and the death rate on the stochastic model. From a biological point of view, little is known about the dependence of the division kernel q with respect to x [25]. Most often in applications it is assumed to be independent of x . In order to obtain the most general result, we assume that q depends on x , and we need to state assumptions about this parameter. Note, however, that the self-similar fragmentation is included in our assumptions. Moreover, although $q(x, \alpha)$ is assumed to be regular with respect to α , more general kernels can be considered, in particular, the following results should hold for self-similar equal mitosis.

For any $x \in (0, 1)$, let $F_x : [0, 1] \rightarrow [0, 1]$ be the cumulative distribution function associated to the law $q(x, \alpha) d\alpha$, that is, for any $u \in [0, 1]$, let

$$F_x(u) = \int_0^u q(x, \alpha) d\alpha$$

and let F_x^{-1} be its inverse function defined by

$$F_x^{-1}(v) = \inf_{u \in [0, 1]} \{F_x(u) \geq v\}.$$

ASSUMPTION 3.1. *The cumulative distribution function F_x satisfies, for any $u \in (0, 1)$ and any $x \leq y$,*

$$x F_x^{-1}(u) \leq y F_y^{-1}(u) \quad \text{and} \quad (1-x) F_x^{-1}(u) \leq (1-y) F_y^{-1}(u).$$

As we will see in Lemma 3.1 below, this assumption corresponds to a coupling condition on the mass of offspring born from individuals of different sizes. We need this condition because our method can be seen as a construction of a coupling of the masses of individuals at each generation in two stochastic processes starting from different initial masses (see our comments below, particularly Remark 3.3).

REMARK 3.1. If F_x^{-1} is such that for any $u \in (0, 1)$, $x \mapsto F_x^{-1}(u) \in C^1([0, M])$, and for any $x \in (0, M)$, satisfies

$$x \partial_x F_x^{-1}(u) \in [-F_x^{-1}(u), 1 - F_x^{-1}(u)],$$

then

$$\partial_x (x F_x^{-1}(u)) = F_x^{-1}(u) + x \partial_x F_x^{-1}(u) \geq 0.$$

Hence $x F_x^{-1}(u)$ is non decreasing. In the same way, $(1-x) F_x^{-1}(u)$ is non decreasing too. Therefore, Assumption 3.1 holds.

EXAMPLES 3.1. *We give some examples which satisfy Assumption 3.1.*

(1) *We consider the following division kernel,*

$$q(x, \alpha) = \frac{\mathbb{1}_{\{l(x) \leq \alpha \leq 1-l(x)\}}}{1 - 2l(x)}.$$

where $l \in C^1([0, M], (0, 1/2))$. Then for $u \in (0, 1)$,

$$F_x^{-1}(u) = (1 - 2u)l(x) + u$$

and, by Remarks 3.1, Assumption 3.1 holds if for any x , $0 \leq x l'(x) + l(x) \leq 1$.

(2) *We can extend the previous example considering the following function q ,*

$$q(x, \alpha) = \frac{(\alpha - l(x))^{\beta(x)}}{C(x)} \mathbb{1}_{\{l(x) \leq \alpha \leq 1/2\}} + \frac{(1 - \alpha - l(x))^{\beta(x)}}{C(x)} \mathbb{1}_{\{1/2 \leq \alpha \leq 1-l(x)\}} \quad (3.1)$$

where $C(x) = 2(1/2 - l(x))^{\beta(x)+1} / (\beta(x) + 1)$ is a normalizing constant. The previous example corresponds to $\beta(x) = 0$ for any $x \in [0, M]$. Then

$$F_x(u) = \frac{1}{2} \left(\frac{u - l(x)}{\frac{1}{2} - l(x)} \right)^{\beta(x)+1} \mathbb{1}_{\{l(x) \leq \alpha \leq 1/2\}} + \left(1 - \frac{1}{2} \left(\frac{1 - u - l(x)}{\frac{1}{2} - l(x)} \right)^{\beta(x)+1} \right) \mathbb{1}_{\{1/2 < \alpha \leq 1-l(x)\}} + \mathbb{1}_{\{1-l(x) < \alpha\}} \quad (3.2)$$

and for any $u \in (0, 1)$

$$F_x^{-1}(u) = \left(\left(\frac{1}{2} - l(x) \right) (2u)^{1/(\beta(x)+1)} + l(x) \right) \mathbb{1}_{\{0 < u \leq 1/2\}}$$

$$+ \left(1 - l(x) - \left(\frac{1}{2} - l(x)\right) (2(1 - u))^{1/(\beta(x)+1)}\right) \mathbb{1}_{\{1/2 < u < 1\}}. \tag{3.3}$$

An example of such functions is given in Figure 3.1.

For $u \in (0, 1/2]$,

$$\partial_x F_x^{-1}(u) = \left(-l'(x) - \left(\frac{1}{2} - l(x)\right) \frac{\beta'(x)}{(\beta(x)+1)^2} \ln(2u)\right) (2u)^{1/(\beta(x)+1)} + l'(x)$$

and for $u \in [1/2, 1)$,

$$\partial_x F_x^{-1}(u) = \left(l'(x) + \left(\frac{1}{2} - l(x)\right) \frac{\beta'(x)}{(\beta(x)+1)^2} \ln(2(1-u))\right) (2(1-u))^{1/(\beta(x)+1)} - l'(x)$$

Assumption 3.1 holds if $0 \leq x \partial_x F_x^{-1}(u) + F_x^{-1}(u) \leq 1$ for any $u \in (0, 1)$, for example if β is a constant function and if $0 \leq l(x) + x l'(x) \leq 1$ for any $x \in (0, M)$.

FIGURE 3.1. Representation of the function q (left), F_x (center) and F_x^{-1} (right) respectively defined by Equations (3.1), (3.2) and (3.3) with $l(x) = 0.25$ and $\beta(x) = 5$.

LEMMA 3.1. Let f be a non-increasing function on $[0, M]$. Then, under Assumption 3.1, the function

$$x \mapsto \int_0^1 q(x, \alpha) f(\alpha x) f((1 - \alpha)x) d\alpha$$

is non-increasing.

Proof. For any $x \in (0, 1)$, define θ_x by $\theta_x = F_x^{-1}(U)$ where U is uniformly distributed on $[0, 1]$. Therefore the law of the variable θ_x is $q(x, \alpha) d\alpha$. By Assumption 3.1,

$$\partial_x(x\theta_x) = \theta_x + x \partial_x F_x^{-1}(U) \geq \theta_x - F_x^{-1}(U) = 0 \quad \text{a.s.}$$

and

$$\partial_x(x(1 - \theta_x)) = 1 - \theta_x - x \partial_x F_x^{-1}(U) \geq 1 - \theta_x - (1 - F_x^{-1}(U)) = 0.$$

Therefore, for any $x < y$ we have $x\theta_x \leq y\theta_y$ a.s. and $x(1-\theta_x) \leq y(1-\theta_y)$ a.s. Hence,

$$\begin{aligned} \int_0^1 q(x, \alpha) f(\alpha x) f((1-\alpha)x) d\alpha &= \mathbb{E}(f(\theta_x x) f((1-\theta_x)x)) \\ &\leq \mathbb{E}(f(\theta_y y) f((1-\theta_y)y)) \\ &= \int_0^1 q(y, \alpha) f(\alpha y) f((1-\alpha)y) d\alpha. \end{aligned}$$

□

REMARK 3.2. Note that the last proof makes use of a probabilistic coupling argument, since we actually prove and use the following property: the pair of random variables $(x\theta_x, x(1-\theta_x))$, where θ_x is distributed as $q(x, \alpha)d\alpha$, is stochastically increasing with respect to x . This means that, for all $x \leq y$, there exists a coupling of the random variables θ_x and θ_y , i.e. two random variables θ'_x and θ'_y with the same laws as θ_x and θ_y can be constructed on the same probability space, such that $x\theta'_x \leq y\theta'_y$ and $x(1-\theta'_x) \leq y(1-\theta'_y)$. Therefore, Assumption 3.1 means that the offspring masses of two individuals reproducing at respective masses x and y can be coupled so that the masses of the offspring are in the same order as those of the parents.

PROPOSITION 3.1. Under Assumption 3.1, if the division rate $b(S, \cdot)$ is non decreasing then the extinction probability $p^S : x \mapsto p^S(x)$ is non increasing.

The assumption that b increases with the mass x of an individual is biologically natural, since a bigger total biomass usually means a bigger fraction of biomass devoted to the bio-molecular mechanisms involved in cellular division. We give below an analytical proof of this proposition, but it can also be proved using probabilistic arguments, as explained in Remark 3.3 below.

Proof. We prove by induction that the function p_n^S is non increasing for any $n \in \mathbb{N}^*$, where p_n^S is given by equation (2.13). Let $0 < x < y < M$. As $A_u^S(x) < A_u^S(y)$, for any $u \geq 0$,

$$p_1^S(x) = D \int_0^\infty e^{-\int_0^t b(S, A_u^S(x)) du - Dt} dt \geq D \int_0^\infty e^{-\int_0^t b(S, A_u^S(y)) du - Dt} dt = p_1^S(y).$$

Then the function p_1^S is non increasing. Let $n \in \mathbb{N}^*$, we assume that the function p_n^S is non increasing.

We can write $p_{n+1}^S(x)$ as

$$p_{n+1}^S(x) = p_1^S(x) + \mathbb{P}_{\delta_x}^S(\{\text{extinction before the } (n+1)\text{-th generation}\} \cap \{\eta_\tau^S \neq 0\}),$$

with

$$\begin{aligned} &\mathbb{P}_{\delta_x}^S(\{\text{extinction before the } (n+1)\text{-th generation}\} \cap \{\eta_\tau^S \neq 0\}) \\ &= \int_0^\infty b(S, A_t^S(x)) e^{-\int_0^t b(S, A_u^S(x)) du - Dt} \\ &\quad \int_0^1 q(A_t^S(x), \alpha) p_n^S(\alpha A_t^S(x)) p_n^S((1-\alpha) A_t^S(x)) d\alpha dt. \end{aligned}$$

The following relation holds

$$p_{n+1}^S(x) = p_1^S(x) + p_{n+1}^S(x | \eta_\tau^S \neq 0) (1 - p_1^S(x))$$

with

$$p_{n+1}^S(x|\eta_\tau^S \neq 0) = \mathbb{P}_{\delta_x^S}^S(\text{extinction before the } (n+1)\text{-th generation} | \eta_\tau^S \neq 0).$$

Since for any $t \geq 0$, $A_{t(x,y)+t}^S(x) = A_t^S(y)$, then, by a change of variable,

$$\begin{aligned} & \int_{t_S(x,y)}^\infty b(S, A_t^S(x)) e^{-\int_0^t b(S, A_u^S(x)) du - Dt} \\ & \quad \int_0^1 q(A_t^S(x), \alpha) p_n^S(\alpha A_t^S(x)) p_n^S((1-\alpha) A_t^S(x)) d\alpha dt \\ = & e^{-\int_0^{t_S(x,y)} b(S, A_u^S(x)) du - Dt_S(x,y)} \int_0^\infty b(S, A_t^S(y)) e^{-\int_0^t b(S, A_u^S(y)) du - Dt} \\ & \quad \int_0^1 q(A_t^S(y), \alpha) p_n^S(\alpha A_t^S(y)) p_n^S((1-\alpha) A_t^S(y)) d\alpha dt \\ = & e^{-\int_0^{t_S(x,y)} b(S, A_u^S(x)) du - Dt_S(x,y)} p_{n+1}^S(y | \eta_\tau^S \neq 0) (1 - p_1^S(y)). \end{aligned} \tag{3.4}$$

For any $t \in [0, t_S(x, y)]$ we have $A_t^S(x) \leq y$. Since we assume that the function p_n^S is non increasing, from Lemma 3.1, we then get

$$\begin{aligned} & \int_0^{t_S(x,y)} b(S, A_t^S(x)) e^{-\int_0^t b(S, A_u^S(x)) du - Dt} \\ & \quad \int_0^1 q(A_t^S(x), \alpha) p_n^S(\alpha A_t^S(x)) p_n^S((1-\alpha) A_t^S(x)) d\alpha dt \\ \geq & \int_0^{t_S(x,y)} b(S, A_t^S(x)) e^{-\int_0^t b(S, A_u^S(x)) du - Dt} dt \int_0^1 q(y, \alpha) p_n^S(\alpha y) p_n^S((1-\alpha) y) d\alpha \\ = & \left(1 - e^{-\int_0^{t_S(x,y)} b(S, A_u^S(x)) du - Dt(x,y)} - D \int_0^{t_S(x,y)} e^{-\int_0^t b(S, A_u^S(x)) du - Dt} dt \right) \\ & \quad \times \int_0^1 q(y, \alpha) p_n^S(\alpha y) p_n^S((1-\alpha) y) d\alpha. \end{aligned} \tag{3.5}$$

Using again that the function p_n^S is non-increasing and Lemma 3.1,

$$\begin{aligned} & \mathbb{P}_{\delta_y^S}^S(\{\text{extinction before the } (n+1)\text{-th generation}\} \cap \{\eta_\tau^S \neq 0\}) \\ \leq & \int_0^\infty b(S, A_t^S(y)) e^{-\int_0^t b(S, A_u^S(y)) du - Dt} dt \int_0^1 q(y, \alpha) p_n^S(\alpha y) p_n^S((1-\alpha) y) d\alpha \\ = & (1 - p_1^S(y)) \int_0^1 q(y, \alpha) p_n^S(\alpha y) p_n^S((1-\alpha) y) d\alpha. \end{aligned}$$

Hence

$$\int_0^1 q(y, \alpha) p_n^S(\alpha y) p_n^S((1-\alpha) y) d\alpha \geq p_{n+1}^S(y | \eta_\tau^S \neq 0).$$

Adding expressions (3.4) and (3.5), and using the last inequality, we then get

$$p_{n+1}^S(x|\eta_\tau^S \neq 0) \geq \left[\frac{1 - D \int_0^{t_S(x,y)} e^{-\int_0^t b(S, A_u^S(x)) du - Dt} dt}{1 - p_1^S(x)} \right]$$

$$- e^{-\int_0^{t_S(x,y)} b(S, A_u^S(x)) du - D t_S(x,y)} \frac{p_1^S(y)}{1 - p_1^S(x)} \Big] p_{n+1}^S(y | \eta_\tau^S \neq 0).$$

Moreover,

$$p_1^S(x) = D \int_0^{t_S(x,y)} e^{-\int_0^t b(S, A_u^S(x)) du - D t} dt + e^{-\int_0^{t_S(x,y)} b(S, A_u^S(x)) du - D t_S(x,y)} p_1^S(y).$$

Hence,

$$p_{n+1}^S(x | \eta_\tau^S \neq 0) \geq p_{n+1}^S(y | \eta_\tau^S \neq 0).$$

Thus,

$$\begin{aligned} p_{n+1}^S(x) - p_{n+1}^S(y) &= p_1^S(x) + p_{n+1}^S(x | \eta_\tau^S \neq 0) (1 - p_1^S(x)) \\ &\quad - p_1^S(y) - p_{n+1}^S(y | \eta_\tau^S \neq 0) (1 - p_1^S(y)) \\ &\geq (p_1^S(x) - p_1^S(y)) (1 - p_{n+1}^S(y | \eta_\tau^S \neq 0)) \geq 0. \end{aligned}$$

This ends the induction. Passing to the limit, we finally get

$$p^S(x) - p^S(y) = \lim_{n \rightarrow \infty} (p_n^S(x) - p_n^S(y)) \geq 0.$$

□

REMARK 3.3. The last result can also be proved by a probabilistic coupling argument as follows. First, for all $x \in (0, M)$, the time of death or division of an individual of mass x can be constructed from an exponential random variable E with parameter 1 as $T_x = \inf\{t \geq 0 : \int_0^t (b(S, A_s^S(x)) + D) ds \geq E\}$. Hence, if $x \leq y$ then $A_{T_x}^S(x) \leq A_{T_y}^S(y)$. Second, we observe that the probability $D / (D + b(S, x))$ of death given death or division occurs for an individual of mass x is non-increasing as a function of x . Hence, using Remark 3.2, given $x \leq y$, we can construct a coupling between the branching processes $(\eta_t^S, t \geq 0)$ with $\eta_0^S = \delta_x$ and $(\hat{\eta}_t^S, t \geq 0)$ with $\hat{\eta}_0^S = \delta_y$ such that the random sets M_1 and \hat{M}_1 of masses at birth of the individuals of the first generation satisfy the following property: the cardinalities of M_1 and \hat{M}_1 are either 0 or 2. If $|\hat{M}_1| = 0$ then $|M_1| = 0$. And if both have cardinality 2, then $M_1 = \{x_1, x_2\}$ and $\hat{M}_1 = \{\hat{x}_1, \hat{x}_2\}$ with $x_1 \leq \hat{x}_1$ and $x_2 \leq \hat{x}_2$.

It then follows by induction that the processes $(\eta_t^S, t \geq 0)$ and $(\hat{\eta}_t^S, t \geq 0)$ can be coupled so that, for all $n \geq 0$, the masses at birth of all the individuals of the n -th generation can be ordered into two vectors $V^n = (x_1^n, \dots, x_{G_n}^n)$ and $\hat{V}^n = (\hat{x}_1^n, \dots, \hat{x}_{\hat{G}_n}^n)$, where G_n and \hat{G}_n are the random sizes of generation n in η^S and $\hat{\eta}^S$ respectively, satisfying the following property: for all n , $G_n \leq \hat{G}_n$ and for all $1 \leq i \leq G_n$, $x_i^n \leq \hat{x}_i^n$. This implies Proposition 3.1 since survival of η^S means that $G_n \geq 1$ for all n and this implies that $\hat{\eta}^S$ also survives. Hence $p^S(x) \geq p^S(y)$.

We now extend the notation of the extinction probability with a dependence in D : let $p^{S,D}(x)$ be the extinction probability of the population evolving in the environment determined by S , with a death rate D and a initial individual with mass x .

PROPOSITION 3.2. *For any $x \in [0, M]$, the function $D \mapsto p^{S,D}(x)$ is non-decreasing.*

Proof. Let $D' > D$.

$$p_1^{S,D}(x) = D \int_0^\infty e^{-\int_0^t b(A_u^S(x)) du - D t} = 1 - \int_0^\infty b(A_u^S(x)) e^{-\int_0^t b(A_u^S(x)) du - D t}$$

$$\leq 1 - \int_0^\infty b(A_u^S(x)) e^{-\int_0^t b(A_u^S(x)) du - D't} = p_1^{S,D'}(x).$$

Hence $D \mapsto p_1^{S,D}(x)$ is non-decreasing. For $n \in \mathbb{N}^*$, let assume that $D \mapsto p_n^{S,D}(x)$ is non-decreasing, then

$$\begin{aligned} p_{n+1}^{S,D}(x) &= 1 - \int_0^\infty b(A_u^S(x)) e^{-\int_0^t b(A_u^S(x)) du - D't} \\ &\quad \left[1 - \int_0^1 q(A_t^S(x), \alpha) p_n^{D,S}(\alpha A_t^S(x)) p_n^{D,S}((1-\alpha) A_t^S(x)) d\alpha \right] dt \\ &\leq 1 - \int_0^\infty b(A_u^S(x)) e^{-\int_0^t b(A_u^S(x)) du - D't} \\ &\quad \left[1 - \int_0^1 q(A_t^S(x), \alpha) p_n^{D',S}(\alpha A_t^S(x)) p_n^{D',S}((1-\alpha) A_t^S(x)) d\alpha \right] dt \\ &= p_{n+1}^{S,D'}(x) \end{aligned}$$

Then for any n , $p_n^{S,D}(x) \leq p_n^{S,D'}(x)$. Passing to the limit,

$$p^{S,D}(x) = \lim_{n \rightarrow \infty} p_n^{S,D}(x) \leq \lim_{n \rightarrow \infty} p_n^{S,D'}(x) = p^{S,D'}(x).$$

□

3.2. Monotonicity properties with respect to S on the stochastic model.

We now study the variations of the survival probability with respect to the environmental parameter S . We need additional assumptions.

ASSUMPTIONS 3.2.

- (1) The division rate function b is non decreasing in the two variables S and x .
- (2) The growth speed g is non decreasing in S :

$$g(S^1, x) \leq g(S^2, x), \quad \forall x \in [0, M], 0 < S^1 < S^2.$$

- (3) For any $x \in (0, M)$, the function $S \mapsto \frac{b(S,x)}{g(S,x)}$ is non increasing.

Assumptions (1) and (2) above are natural from the biological point of view since a bigger total biomass means a bigger fraction of biomass devoted to division and a larger amount of resources means a more efficient growth and division of cells. Assumption (3) means that the growth rate increases faster in S than the division rate. This excludes that, with increasing S , a faster division produces individuals too small to grow and reproduce. Note that these assumptions are satisfied if, for instance, b does not depend on the variable S , and if g is of the form $g(S, x) = \mu(S) \tilde{g}(x)$ where μ is a non decreasing function. For example, in Monod kinetics [23], $\mu(S) = \mu_{\max} \frac{S}{K+S}$ where μ_{\max} and K are constants. The form $g(S, x) = \mu(S) \tilde{g}(x)$ means that the resource concentration S influences the speed of growth of bacteria independently of the way x influences growth. In other words, the flow $t \mapsto A_t^{S'}(x)$ is just a proportional time change of $t \mapsto A_t^S(x)$ for all S, S' .

THEOREM 3.1. Under Assumptions 3.1 and 3.2, we have for any $x \in (0, M)$

$$\mathbb{P}_{\delta_x}^{S^1}(\text{survival}) \leq \mathbb{P}_{\delta_x}^{S^2}(\text{survival}), \quad \forall 0 < S^1 \leq S^2.$$

In other words, for the chemostat model, under the assumptions of the previous theorem, the higher the substrate concentration in the chemostat at the mutation time, the higher the survival probability.

REMARK 3.4. Following Remark 3.3, the last result could also be proved by probabilistic coupling arguments. These arguments would actually only require the assumption that, for all $x \leq y$ and $S_1 \leq S_2$, there exists a coupling between the sets M_1^{x,S_1} and M_1^{y,S_2} of biomasses at birth of the individuals of the first generation in the respective branching processes $(\eta_t^{S_1}, t \geq 0)$ with $\eta_0^{S_1} = \delta_x$ and $(\eta_t^{S_2}, t \geq 0)$ with $\eta_0^{S_2} = \delta_y$. It would then be enough that the coupling satisfies the following property: $|M_1^{y,S_2}| = 0$ implies $|M_1^{x,S_1}| = 0$, and when both have cardinality 2, then $M_1^{x,S_1} = \{x_1, x_2\}$ and $M_1^{y,S_2} = \{y_1, y_2\}$ with $x_1 \leq y_1$ and $x_2 \leq y_2$. The proof of Theorem 3.1 given below actually consists in checking that the coupling assumption above is implied by Assumptions 3.1 and 3.2. However, this coupling assumption is hard to check in practice and this is why we chose to give an analytical proof based on the Assumptions 3.1 and 3.2, which are stronger, but easier to check.

Of course, Theorem 3.1 is certainly valid under weaker assumptions, for example if b or g are not monotonic with respect to S , but our probabilistic approach requires coupling assumptions like the one stated in this remark, so the method would not extend easily to such cases.

Proof. For any $y \in (0, M)$ the function $S \mapsto g(S, y)$ is non decreasing, then $A_u^{S_1}(x) \leq A_u^{S_2}(x)$ for any $u \geq 0$. Moreover the function $(S, x) \mapsto b(S, x)$ is non decreasing in the two variables S and x , then we have

$$p_1^{S_1}(x) - p_1^{S_2}(x) = D \int_0^\infty e^{-Dt} \left[e^{-\int_0^t b(S_1, A_u^{S_1}(x)) du} - e^{-\int_0^t b(S_2, A_u^{S_2}(x)) du} \right] dt \geq 0.$$

The function $S \mapsto p_1^S(x)$ is then non increasing for any $x \in (0, M)$. Let $n \in \mathbb{N}^*$, we assume that the function $S \mapsto p_n^S(x)$ is non increasing for any $x \in (0, M)$.

The function $t \mapsto \int_0^t (b(S, A_u^S(x)) + D) du$ is a bijection from $[0, \infty[$ to $[0, \infty[$. Hence, for $X \geq 0$, there exists a unique $T_x^S(X)$ such that $X = \int_0^{T_x^S(X)} (b(S, A_u^S(x)) + D) du$. By the change of variable $X = \int_0^t (b(S, A_u^S(x)) + D) du$ in equation (2.13), we obtain

$$p_{n+1}^S(x) = \int_0^\infty \left[\frac{D}{b(S, A_{T_x^S(X)}^S(x)) + D} + \frac{b(S, A_{T_x^S(X)}^S(x))}{b(S, A_{T_x^S(X)}^S(x)) + D} \Psi_n^{S,x}(X) \right] e^{-X} dX$$

with

$$\Psi_n^{S,x}(X) = \int_0^1 q\left(A_{T_x^S(X)}^S(x), \alpha\right) p_n^S\left(\alpha A_{T_x^S(X)}^S(x)\right) p_n^S\left((1-\alpha) A_{T_x^S(X)}^S(x)\right) d\alpha. \tag{3.6}$$

Moreover, for all $X \geq 0$, for $S_1 \leq S_2$, by the changes of variable $A_u^{S_i}(x) = y$ for $i = 1, 2$ and by Assumption 3.2-(3), we have

$$\begin{aligned} \int_x^{A_{T_x^{S_2}}^{S_2}(x)} \frac{b(S_2, y) + D}{g(S_2, y)} dy &= X = \int_x^{A_{T_x^{S_1}}^{S_1}(x)} \frac{b(S_1, y) + D}{g(S_1, y)} dy \\ &\geq \int_x^{A_{T_x^{S_1}}^{S_1}(x)} \frac{b(S_2, y) + D}{g(S_2, y)} dy, \end{aligned}$$

therefore $A_{T_x^{S^2}}^{S^2}(x) \geq A_{T_x^{S^1}}^{S^1}(x)$. We deduce from Lemma 3.1 and Proposition 3.1 that $\Psi_n^{S^1,x}(X) \geq \Psi_n^{S^2,x}(X)$. Hence, using $\Psi_n^{S^1,x}(X) \geq \Psi_n^{S^2,x}(X)$ in the expression of $p_{n+1}^{S^1}$, subtracting the expression of $p_{n+1}^{S^2}$ and factorizing the terms, we obtain

$$p_{n+1}^{S^1}(x) - p_{n+1}^{S^2}(x) \geq \int_0^\infty \left[\frac{D}{b(S^1, A_{T_x^{S^1}}^{S^1}(x)) + D} - \frac{D}{b(S^2, A_{T_x^{S^2}}^{S^2}(x)) + D} \right] (1 - \Psi_n^{S^2,x}(X)) e^{-X} dX$$

and as $\Psi_n^{S^2,x}(X) \leq 1$, by Assumptions 3.2-(1), $p_{n+1}^{S^1}(x) \geq p_{n+1}^{S^2}(x)$. Finally, passing to the limit, we get

$$p^{S^1}(x) - p^{S^2}(x) = \lim_{n \rightarrow \infty} (p_n^{S^1}(x) - p_n^{S^2}(x)) \geq 0.$$

□

3.3. Properties on the variations of the eigenvalue. Until now, we only studied the probability of survival of the branching process η^S . The underlying coupling arguments require consideration of the population state at each generation in a process where generations actually overlap. This is why such an approach is hard to apply directly to the integro-differential eigenvalue problem, where the notion of generations is difficult to define. However, the link between the stochastic and deterministic problems stated in Theorem 2.1 allows one to extend the monotonicity properties of Theorem 3.1 to the eigenvalue Λ_S , as proved below. The next corollary is a direct consequence of Theorems 2.1 and 3.1.

COROLLARY 3.1. *Under Assumptions 3.1 and 3.2,*

- (1) *if there exists $S_1 > 0$ such that $\Lambda_{S_1} > 0$, then $\Lambda_{S_2} > 0$ for any $S_2 > S_1$;*
- (2) *if there exists $S_1 > 0$ such that $\Lambda_{S_1} \leq 0$, then $\Lambda_{S_2} \leq 0$ for any $S_2 < S_1$.*

This Corollary allows us to deduce the following result about variation of the eigenvalue with respect to S .

COROLLARY 3.2. *Under Assumptions 3.2, the function $S \mapsto \Lambda_S$ is non decreasing.*

The monotonicity of b is important to obtain the monotonicity of the eigenvalue (and of the survival probability). For example, one can imagine cases where a fast growth rate g transports individuals to big masses and if the division rate is low for high values, the monotonicity of the eigenvalue does not hold (see [2] for non monotonic examples).

Proof. Let $S^* > 0$ be fixed. We set $D' = D + \Lambda_{S^*} > 0$. Let Λ'_S be the eigenvalue of the following eigenproblem:

$$\partial_x(g(S,x)\hat{u}'_S(x)) + (b(S,x) + D' + \Lambda'_S)\hat{u}'_S(x) = 2 \int_x^M \frac{b(S,z)}{z} q\left(z, \frac{x}{z}\right) \hat{u}'_S(z) dz.$$

For $S = S^*$, we have $\Lambda'_{S^*} = 0$, then from Corollary 3.1, for any $S \leq S^*$, $\Lambda'_S \leq 0$. Moreover

$$\Lambda'_S = \Lambda_S + D - D' = \Lambda_S - \Lambda_{S^*}.$$

Hence $\Lambda_S \leq \Lambda_{S^*}$.

□

3.4. Extensions and concluding remarks. The previous method can be applied for more general g , for which the growth in one environment is larger than the growth in the other one for all masses. A particular case is given in the following corollary.

COROLLARY 3.3. *We assume that the division rate function b does not depend on the variable S and is non decreasing in the variable x and that the growth speed g is of the form $g(S, x) = \mu(S)\tilde{g}(x)$, where $g(S, x) > 0$ for any $x \in (0, M)$ and $\tilde{g} \in C[0, M] \cap C^1(0, M)$ is such that $\tilde{g}(0) = \tilde{g}(M) = 0$. Then, we have*

$$\mathbb{P}_{\delta_x}^{S^1}(\text{survival}) \leq \mathbb{P}_{\delta_x}^{S^2}(\text{survival}) \iff \mu(S^1) \leq \mu(S^2)$$

and

$$\Lambda_{S^1} \leq \Lambda_{S^2} \iff \mu(S^1) \leq \mu(S^2).$$

More generally, the following result states the link between the comparison of the survival probability and the comparison of the eigenvalue.

We extend the notations of the survival probability $\mathbb{P}_{\delta_x}^{S,D}(\text{survival})$ and the eigenvalue Λ_S^D with a dependence to the death rate D .

PROPOSITION 3.3. *Let $S_1, S_2 > 0$. If for any $x \in [0, M]$ and for any $D > 0$, we have $\mathbb{P}_{\delta_x}^{S_1,D}(\text{survival}) \geq \mathbb{P}_{\delta_x}^{S_2,D}(\text{survival})$, then*

$$\forall D > 0, \quad \Lambda_{S_1}^D \geq \Lambda_{S_2}^D.$$

The condition on the survival probability stated in the previous theorem could of course be obtained under the appropriate coupling assumptions (as in Remark 3.3), but it seems hard to find general practical conditions on the parameters of the model ensuring such a property. Note also that this coupling method could be applied to the case where the division distribution q also depends on the variable S . The results of Section 3.1 would remain true as, for this section, the substrate concentration is fixed. The difficulties are in the control of the variation in S of $\Psi_n^{S,x}$ defined by equation (3.6).

Proof. Let $S_1 > 0$. We set $D' = D + \Lambda_{S_1}^D > 0$. Let Λ'_S be the eigenvalue associated to the eigenproblem

$$\partial_x(g(S, x)\hat{u}'_S(x)) + (b(S, x) + D' + \Lambda'_S)\hat{u}'_S(x) = 2 \int_x^M \frac{b(S, z)}{z} q\left(\frac{x}{z}\right) \hat{u}'_S(z) dz.$$

For $S = S_1$, $\Lambda'_{S_1} = 0$, we then deduce, from Theorem 2.1, that $\mathbb{P}_{\delta_x}^{S_1,D'}(\text{survival}) = 0$ and then, by assumption, that $\mathbb{P}_{\delta_x}^{S_2,D'}(\text{survival}) = 0$. From Theorem 2.1 $\Lambda'_{S_2} \leq 0$. Moreover

$$\Lambda'_{S_2} = \Lambda_{S_2}^D + D - D' = \Lambda_{S_2}^D - \Lambda_{S_1}^D$$

hence

$$\Lambda_{S_2}^D \leq \Lambda_{S_1}^D.$$
